## Abstract

Behavioral responses of beaked whales (family Ziphiidae) to naval use of mid-frequency active sonar (MFAS) have been quantified for some species and regions. We describe the effects of MFAS on the probability of detecting diving groups of Blainville's beaked whales on the US Navy Pacific Missile Range Facility (PMRF) in Hawaii and compare our results to previously published results for the same species at the Atlantic Undersea Test and Evaluation Center (AUTEC) in the Bahamas. We used passive acoustic data collected at bottom-mounted hydrophones before and during six naval training exercises at PMRF along with modelled sonar received levels to describe the effect of training and MFAS on foraging groups of Blainville's beaked whales. We used a multi-stage generalized additive modelling approach to control for the underlying spatial distribution of vocalizations under baseline conditions. At a MFAS received level of 150 dB re 1  $\mu$ Pa the probability of detecting groups of Blainville's beaked whales decreased by 78% (95% CI 62%-100%) compared to periods when general training activity was ongoing and by 92% (95% CI 87%-100%) compared to baseline conditions. Our results indicate a more pronounced response to naval training and MFAS than has been previously reported. [196/200]

## KEYWORDS

Blainville's beaked whales, *Mesoplodon densirostris*, mid-frequency active sonar, passive acoustic data, behavioral response, generalized additive model

# 1 Introduction

Beaked whales (family Ziphiidae) are a group of deep-diving cetaceans that rely on sound to forage, navigate, and communicate (Aguilar de Soto et al., 2012; Johnson et al., 2004; Macleod and D’Amico, 2006) and are sensitive to anthropogenic noise (Southall et al., 2016). Multiple mass strandings of beaked whales have been associated with high-intensity anthropogenic sound sources including naval sonar (Bernaldo de Quirós et al., 2019; D’Amico et al., 2009). These acute events have motivated research into whether and how beaked whales respond to different types and intensities of anthropogenic noise (e.g., Aguilar de Soto et al., 2006; Cholewiak et al., 2017; Tyack et al., 2011). Anthropogenic sound can disrupt the patterned foraging dive cycles of beaked whales (Falcone et al., 2017), potentially leading to cumulative sublethal impacts resulting from reduced foraging opportunities (New et al., 2013; Pirodda et al., 2018), or to symptoms similar to decompression sickness that can lead to injury or death (Sascha K. Hooker et al., 2009; S. K. Hooker et al., 2012).

Research on Blainville’s beaked whales (*Mesoplodon densirostris*) on a U.S. Navy range in the Bahamas has shown decreases in time spent foraging and movement away from naval sonar sources (Joyce et al., 2019; Tyack et al., 2011). Naval sonar can be broadcast from various platforms, including vessels, helicopters, buoys, submarines, and torpedoes (Harris et al., 2019; U.S. Department of the Navy, 2018). Most research has focused on the impacts of mid-frequency active sonar (MFAS) broadcast from naval vessels. Separately, researchers have shown that, in the absence of MFAS, beaked whales may alter their behavior in response to vessel noise (Aguilar de Soto et al., 2006; Pirodda et al., 2012).

The U.S. Navy is interested in quantifying the effects of sonar on beaked whales for the purpose of risk assessments and permitting associated with training activities (e.g., U.S. Department of the Navy, 2017). There are different experimental and analytical ways of quantifying responses to sonar (see Harris et al., 2018 for a review). Here, we focus on analyses of observational data from cabled hydrophone arrays collected concurrently with

naval training exercises. Examples of these from previous studies include McCarthy et al. (2011) who used data from the cabled hydrophone array at the U.S. Navy’s Atlantic Undersea Test and Evaluation Center (AUTEK) in the Bahamas collected before, during, and after naval training exercises involving MFAS. The authors used separate generalized additive models (GAMs) for each period, and modelled the acoustic detection of groups of Blainville’s beaked whales (group vocal periods; GVPs) as a function of location on the range and time. They found that the number of GVPs was lower during the exercises than before or after. Building on this work, Moretti et al. (2014) used a GAM to model the presence or absence of GVP starts within 30-min periods (i.e., whether or not a GVP started within each 30-min period) on the AUTEK range as a smooth function of MFAS received level. They compared the expected probability of detecting animals when no sonar was present to the expected probability of detecting animals across sonar received levels to estimate the probability of disturbance. They found that the probability of detecting groups of Blainville’s beaked whales was reduced by 50% at 150 dB re  $1\mu\text{Pa}$ , which they interpreted as a 50% probability of disturbance.

Our primary objective was to replicate the effort of Moretti et al. (2014) with the same species on a different U.S. Navy training range in a different oceanic environment. We used a spatially-referenced dataset of Blainville’s beaked whale foraging dives recorded at the PMRF off the island of Kauai, Hawaii (Fig. 1). Passive acoustic detections of the presence or absence of GVP starts within 30-min periods were collected via a cabled hydrophone array at PMRF before and during training exercises involving MFAS broadcast from navy ships.

Unlike AUTEK, which is situated in a deep isolated basin surrounded by steep slopes, the Pacific Missile Range Facility (PMRF) in Hawaii is located on the side of an ancient volcano, with a steep slope to the deep ocean floor. Previous work in this region has shown that Blainville’s beaked whales are present year-round at this site, prefer sloped habitats, and that acoustic detections decrease during multi-day training events involving MFAS (Henderson

et al., 2016; Manzano-Roth et al., 2016). As we expected the density of Blainville’s beaked whales at PMRF to be low and spatially variable, our methods needed to explicitly account for differences in underlying beaked whale presence across the range. An additional objective was to isolate the effect of general training activity from the effect of MFAS, so that beaked whale response to MFAS could be quantified relative to pre-training baseline periods and to periods when general training activities were present on the range.

## 2 Methods

### 2.1 Data Collection and Processing

#### 2.1.1 Acoustic detection of beaked whales

The Pacific Missile Range Facility (PMRF) is an instrumented U.S. Navy range extending 70 km NW of the island of Kauai, Hawaii and encompassing 2,800 km<sup>2</sup>. The range includes a cabled hydrophone array (Fig. 1) with hydrophones at depths ranging from approximately 650 m to 4,700 m. We used data collected before and during six Submarine Command Courses (SCCs) at PMRF. SCCs are training exercises that occur biannually in February and August and typically last 6-7 days. Acoustic recordings were made for a minimum of two days before each SCC as well as during the exercise. During data collection, hydrophones sampled at a rate of 96 kHz. Up to 62 hydrophones were recorded simultaneously by the Naval Information Warfare Center (NIWC).

A beaked whale detector from the Navy Acoustic Range WHale AnaLysis (NARWHAL) algorithm suite (Martin et al., 2020) was run on the recordings. This detector first compared signal-to-noise ratio (SNR) thresholds within the expected frequency range of beaked whale clicks (16-44 kHz) versus the bandwidth outside the click in a running 16,384-pt fast Fourier transform (FFT) spectrogram. The detected clicks were then passed to a 64-pt FFT stage

117 that measured power, bandwidth, slope, and duration characteristics to classify the clicks to  
118 species. This process was followed by an automated routine in MATLAB (*MATLAB*, 2017)  
119 to group detections of individual beaked whale echolocation clicks into GVPs (Henderson et  
120 al., 2016). If a group of whales was detected by more than one hydrophone, the GVP was  
121 assigned to the hydrophone that recorded the most clicks. The data were then aggregated  
122 to indicate the presence or absence of the start of a GVP for each hydrophone within each  
123 half-hour period. We used half-hour periods to approximate the typical vocal period of  
124 Blainville’s beaked whales during deep foraging dives (Tyack et al., 2006).

Figure 1: Map of hydrophones (black points) at the Pacific Missile Range Facility near the island of Kauai, Hawaii. For security reasons, the approximate rather than exact locations are shown here. Color scale indicates bathymetry. Inset map shows range location (black rectangle) relative to the main Hawaiian Islands.

### 2.1.2 Modelling received levels of hull-mounted mid-frequency active sonar

For security reasons, classified data regarding activity that occurred on the range during each SCC was passed from PMRF to one author with clearance (E.E.H.). These data indicated the locations of the ships during the training periods and the start and stop times of each individual training event. However, no information was provided on the start and stop of sonar use; hence, periods of active sonar were determined from the range hydrophone

131 recordings by running a sonar detector from the NARWHAL algorithm suite tuned to MFAS.  
132 The hydrophone recordings cannot reliably be used to determine received level when the  
133 received level exceeds 140 dB re. 1  $\mu$  Pa due to voltage constraints at the analog to digital  
134 recorder interface. Additionally, the hydrophones are mostly 4-5 km deep, whereas Blainville's  
135 beaked whales begin clicking when they have reached depths of approximately 200-500 m and  
136 spend most of their foraging dive at depths of 1-1.5 km (Johnson et al., 2004, 2006; Madsen  
137 et al., 2013). Therefore, we used an acoustic modeling approach to estimate the maximum  
138 received level of hull-mounted MFAS during each half-hour period around the location of  
139 each hydrophone at a depth of 1,000 m.

140 First, the locations of all surface ships were noted at the start of each half-hour period and  
141 the closest ship to each hydrophone was determined. MFAS propagation was modelled using  
142 the parabolic equation propagation model in the program Peregrine [OASIS; Heaney and  
143 Campbell (2016)]. Acoustic transmission loss was estimated using a 200 Hz band around the  
144 center frequency of the sonar (3.5 kHz). A nominal source level of 235 dB re. 1  $\mu$  Pa @ 1 m  
145 was assumed (U.S. Department of the Navy, 2008). The transmission loss was estimated along  
146 the radial from the ship to the hydrophone from a distance of 1 km before the hydrophone to  
147 1 km past the hydrophone in 200 m increments and converted to received levels based on  
148 the source level of the sonar. The maximum modeled received level along that radial was  
149 determined for each hydrophone and half-hour period. However, if the distance between  
150 the ship and the hydrophone was less than the depth of the water column, the parabolic  
151 equation would overestimate transmission loss at that angle. In these cases, a simple sonar  
152 equation was used to estimate transmission loss instead [CITE]. For hydrophones shallower  
153 than 1,000 m the received level was estimated at a point 20 m above the sea floor with a +/-  
154 10 m buffer, while for hydrophones deeper than 1,000 m the received level was estimated at a  
155 depth of 1,000 m with a +/- 10 m buffer. This process resulted in an estimate of received  
156 level for each hydrophone and half-hour period. Uncertainty in the modeled received levels

was not considered.

## 2.2 Spatial Modelling

### Summary

We first used tessellation to determine the area effectively monitored by each hydrophone. Then, we used a three-stage GAM approach to control for the underlying spatial distribution of Blainville’s beaked whales when modelling the effects of training activities and of MFAS. For the first model (M1), we used pre-activity data to create a spatial model of the probability of GVPs across the range prior to the onset of naval activity. We used the predicted values from this first model as an offset in a second model (M2) created using data from when naval activity was present on the range, but MFAS was not. We then used the predicted values from this second model as an offset in a third model (M3) created using data when naval activity and MFAS were present on the range. Finally, we used posterior simulation to calculate confidence intervals and quantified the change in the probability of detecting GVPs when naval activity was present and across received levels of MFAS. Analyses were undertaken in R (R Core Team, 2018). Code and data are available at [CITE zenodo repo].

### 2.2.1 Determining hydrophone effort

For security reasons, randomly jittered locations and depths of hydrophones at PMRF were used. We projected the coordinates of each hydrophone into Universal Transverse Mercator Zone 4. Because the beaked whale detection algorithm assigned GVPs to the hydrophone that recorded the most echolocation clicks, and because the spatial separation of the hydrophones was not uniform, effort was not the same for all hydrophones. This meant that some hydrophones may have detected more GVPs because they were further away from other hydrophones, not because they were located in higher-density areas. To account for this, we used a Voronoi tessellation implemented in the R package `deldir` (Turner, 2019) to

define a tile for each hydrophone that contained all points on the range that were closest to that hydrophone. We assumed that beaked whale groups occur within the tessellation tile of the hydrophone to which the GVP is assigned, and that the area of each tessellation tile influences the GVP detection rate at that hydrophone. For hydrophones on the outside of the range, i.e., not surrounded by other hydrophones, we used a cutoff radius of 6,500 m to bound the tessellation tiles. This distance was based on the estimated maximum detection distance of individual Blainville’s beaked whale clicks at a U.S. Naval range in the Bahamas (Marques et al., 2009). Different combinations of hydrophones were used during different SCCs, so separate tessellations were created for each SCC.

### 2.2.2 M1: Modelling the pre-activity probability of dive detection

In the first model, we used data collected prior to SCCs, when no naval ships were present on the range and no other naval activity was known to occur, to model the spatial distribution of GVP detections across the range. Because of the way that GVPs were assigned to hydrophones (see Section 2.1.1) the data were not continuous in space. To account for this, we used a Markov random field (MRF) implemented in the R package `mgcv` (Wood, 2017) to model the spatial distribution of GVP detections. Markov random fields (Rue and Held, 2005) model correlation in space between discrete spatial units (henceforth, “tiles”). The correlation between two tiles is dictated by distance, as measured by the number of other tiles one needs pass through to travel between two tiles (“hops”); correlation is strongest between a tile and its direct neighbors (those tiles it shares a border with) and decreases with additional hops. This was appropriate for our data as we did not know where in each tile a given GVP occurred, but we assumed that it did occur in that tile.

We modelled the probability of a GVP at tile  $i$  during SCC  $s$  ( $\mu_{M1,i,s}$ ) as a Bernoulli random

variable. The linear predictor (on the logit scale) was given as:

$$\text{logit}(\mu_{\mathbf{M1},i,s}) = \beta_{\mathbf{M1},0} + f(\mathbf{MRF}_{i,s}) + f(\mathbf{Depth}_i) + \log_e A_{i,s} \quad (1)$$

where  $\beta_{\mathbf{M1},0}$  is an intercept,  $f(\mathbf{MRF}_{i,s})$  denotes the Markov random field used to smooth space in the  $s^{\text{th}}$  SCC,  $f(\mathbf{Depth}_i)$  is a smooth of depth at the location of each hydrophone (using a thin plate spline; Wood (2003)) and  $\log_e A_{i,s}$  is an offset for the area (in  $\text{km}^2$ ) of each tile for each SCC,  $A_{i,s}$ . The offset term accounts for changes in probabilities of GVP detection due to the different areas monitored by each hydrophone. Because the hydrophone tessellation changed between SCCs (as there were different sets of hydrophones recorded during each SSC), separate MRFs were used for each SCC, but a single smoothing parameter was estimated across all MRFs. This allowed for different spatial smooths for each SCC, but constrained the smooths to have the same amount of wiggleness. The smooth of depth was shared across SCCs. We used this model to predict the baseline probability of a GVP detection at each hydrophone.

### 2.2.3 M2: Modelling the effect of Naval activity

For the second model, we used data collected prior to the onset of hull-mounted MFAS used during SCCs, when other naval training activities occurred at PMRF. Various vessels were present on the range during these periods, and other noise sources, including range-tracking pingers, torpedoes, and submarines, may have been present. We used data collected when training activity was present on the range, but hull-mounted MFAS was not used, to model the effect of general naval activity on beaked whale GVPs.

We used the predicted baseline probability of a GVP detection at each hydrophone from **M1** as an offset to control for the underlying spatial distribution of GVPs. The model for the data when naval activity was present was intercept-only, with an offset derived from **M1**. This meant that the spatial distribution of GVPs was not allowed to change, but that we expected

a uniform relative change in GVPs when naval activity was present. We again modelled the probability of GVP presence at tile  $i$  ( $\mu_{\mathbf{M2},i}$ ) as a Bernoulli random variable, with the following linear predictor:

$$\text{logit}(\mu_{\mathbf{M2},i,s}) = \beta_{\mathbf{M2},0} + \log_e \xi_{\mathbf{M1},i,s}, \quad (2)$$

221 where  $\beta_{\mathbf{M2},0}$  is an intercept and  $\xi_{\mathbf{M1},i,s}$  is the prediction (on the logit scale) for tile  $i$  during  
 222 SCC  $s$  using model **M1**, included as an offset term.

#### 223 **2.2.4 M3: Modelling the effect of hull-mounted MFAS**

For the third model, we used data collected when hull-mounted MFAS was present on the range to model the effect of sonar on beaked whales. We excluded data collected during breaks in training activities when sonar was not being used. The probability of a GVP when sonar was present was modeled as a function of the maximum received level (modeled at each hydrophone for each half-hour period; see section 2.2.1). We assumed that as the maximum received level increased, the probability of dives decreased and modeled this using a monotonically decreasing smooth implemented in the R package `scam` (Pya and Wood, 2015). To ensure that the model predictions were the same at a maximum received level of 0 dB and when ships were not present, we did not include an intercept. Probability of GVP presence at tile  $i$  ( $\mu_{\mathbf{M3},i}$ ) was modelled as a Bernoulli random variable where the linear predictor was:

$$\text{logit}(\mu_{\mathbf{M3},i,s}) = f(\text{MaxRL}_{i,s}) + \log_e \xi_{\mathbf{M2},i,s}, \quad (3)$$

224 where  $f(\text{MaxRL}_{i,s})$  was modeled as a monotonic decreasing smooth,  $\xi_{\mathbf{M2},i,s}$  denotes the prediction  
 225 (on the logit scale) for tile  $i$  during SCC  $s$  when naval training activities were present on the  
 226 range using model **M2**.

### 2.2.5 Uncertainty propagation

We used posterior simulation [sometimes referred to as a parametric bootstrap; Wood et al. (2017)] to propagate uncertainty through M1, M2, and M3. This consisted of sampling from the posterior distribution of the parameters for each model in turn, calculating predictions using these parameters and then refitting the subsequent model with updated offsets. Following this procedure through from M1 to M2 to M3 incorporated uncertainty from each model in the final predictions of the probability of detecting a GVP given different combinations of covariates.

The prediction grid contained all possible combinations of covariates within the realized covariate space; i.e., each hydrophone for each SCC with associated location, hydrophone depth, and area of the tessellation tile, presence/absence of naval activity, and, if naval activity was present, then either sonar absence or sonar received level. Based on the resulting final posterior distribution of results (for model M3) we used 2.5%, 50%, and 97.5% quantiles to obtain median predictions and credible intervals (CIs). Mathematical details of the procedure are given in Appendix S1.

### 2.2.6 Quantifying the change in probability of GVPs

Finally, we calculated the expected change in the probability of detecting a GVP at each hydrophone  $P(\text{GVP})$  relative to either the probability of detecting a GVP when no general naval training activity was present and no MFAS was present ( $\Delta_{M3':M1'}$ ), or relative to probability of detecting a GVP when general naval training activity was present but no MFAS was present ( $\Delta_{M3':M2'}$ ) with uncertainty.

Using the  $N_b$  posterior samples, we calculated the expected  $P(\text{GVP})$  under each set of covariates as

$$P(\text{GVP}) = \text{logit}^{-1}(\mu_{M'}), \quad (1)$$

for each  $\mathbf{M}' = \mathbf{M1}', \mathbf{M2}',$  and  $\mathbf{M3}'$ . Then, we calculated the change in  $P(\text{GVP})$  for each set of covariates between  $\mathbf{M3}'$  and  $\mathbf{M1}'$  ( $\Delta_{\mathbf{M3}':\mathbf{M1}'}$ ) and between  $\mathbf{M3}'$  and  $\mathbf{M2}'$  ( $\Delta_{\mathbf{M3}':\mathbf{M2}'}$ ) for each realization of the posterior simulation.

$$\Delta_{\mathbf{M3}':\mathbf{M1}'} = \frac{P(\text{GVP})_{\mathbf{M3}'} - P(\text{GVP})_{\mathbf{M1}'}}{P(\text{GVP})_{\mathbf{M1}'}} \quad (2)$$

$$\Delta_{\mathbf{M3}':\mathbf{M2}'} = \frac{P(\text{GVP})_{\mathbf{M3}'} - P(\text{GVP})_{\mathbf{M2}'}}{P(\text{GVP})_{\mathbf{M2}'}} \quad (3)$$

For each received level we calculated the 2.5th, 50th, and 97.5th quantiles of  $\Delta_{\mathbf{M3}':\mathbf{M1}'}$  and  $\Delta_{\mathbf{M3}':\mathbf{M2}'}$  to create 95% CIs of change in  $P(\text{GVP})$  across possible received levels. We consider that the probability of disturbance is equal to 1 wherever the 95% CI does not include 0, and 0 otherwise.

## 3 Results

### 3.1 Results of Data Collection and Processing

Data were collected before and during six SCCs: two each in 2013, 2014, and 2017 (Table 1). The number of hydrophones for which recordings were available for each SCC varied from 49 to 61. A total of 190,928 30-min observations were made.

The exact timing of activities during these exercises varied (Fig. 2). For most SCCs, pre-activity data were available immediately preceding the onset of Naval training activity; however, in February 2013 the only available pre-activity data were collected almost a month prior to the onset of Naval training activity. In some SCCs, weekends or other breaks in training resulted in a break in training activity on the range during the days preceding MFAS use. MFAS was used for 3-4 days during each training event.

Table 1: Number of hydrophones (HPs) used and number of observations made (no. 30-min periods) during each Submarine Commander Course before the exercise began, when naval activity was present, and when Naval activity and mid-frequency active (MFA) sonar were present.

SCC	HPs	Pre-Activity	Nav. Activity	MFA Sonar
Feb13	61	114	193	124
Aug13	61	209	115	97
Feb14	60	513	111	129
Aug14	61	263	120	128
Feb17	59	450	97	108
Aug17	49	270	106	113

Figure 2: Timeseries of six recorded Naval training activities at the Pacific Missile Range Facility. The timeseries are aligned relative to the first day that mid-frequency active (MFA)

Across all SCCs, hydrophones, and conditions, a total of 2,312 GVPs were identified. The average probability of detecting a GVP during each half-hour period was therefore 1.2%. The spatial distribution of GVPs differed during the pre-activity phases of SCCs (Fig. S2.1; top panel).

Modelled maximum received levels ranged from 38 to 186 dB re.  $1 \mu$  Pa, with a median value when MFAS was present of 147 dB re.  $1 \mu$  Pa. The intensity and spatial distribution of MFAS received levels varied across the range and across SCCs (Fig. S2.2).

Based on the observed data, the probability of detecting a GVP changed by -57% when general naval training activity was present compared to when naval activity was absent, by -47% when naval activity and MFAS were present compared to when only naval activity was present, and by -77% when naval activity and MFAS were present compared to when neither naval activity nor sonar were present (Fig. S2.3).

## 3.2 Results of spatial modelling

We created separate tessellations for each SCC (Fig. S2.4). In August 2017, data were available from fewer hydrophones, and so in some cases the tessellated tiles, with bounding radius of 6,500 m, did not completely cover the range. Hydrophone depths varied from 648 to 4716 m.

M1 fitted a spatial model of  $P(\text{GVP})$  to data collected prior to the onset of naval training activity. This model used a MRF smooth to account for the spatial structure of the range and a spline on depth, with an offset for the log of the area effectively monitored by each hydrophone. Both the MRF and spline on depth were significant at the  $\alpha = 0.05$  level ( $p$ -value  $< 2\text{E-}16$ ). The model explained 14.1% of deviance in the dataset, and visual inspection of observed versus predicted values indicated a good fit to the data (Fig. S2.5). The model M1 predicted highest  $P(\text{GVP})$  at hydrophone depths between 1,500 and 2,000 m (Fig. S2.6).

289 M2 used the predicted values from M1 as an offset and fitted a model of to data when naval  
 290 activity was ongoing, as indicated by the presence of naval ships on the range. This model  
 291 was intercept-only, and  $P(\text{GVP})$  when naval activity was ongoing was significantly different  
 292 from the baseline period at the  $\alpha = 0.05$  level ( $p\text{-value} < 2\text{E-}16$ ). The expected  $P(\text{GVP})$   
 293 decreased by a median of 64% (95% CI 59% - 68%) when naval activity was present compared  
 294 to when it was absent.

295 M3 used the predicted values from M2 as an offset and fitted a model to data when naval  
 296 activity and MFAS were present. This model used a monotonically decreasing spline on  
 297 modelled MFAS received level (Fig. S2.7) and did not include an intercept term. The smooth  
 298 on MFAS received level was significant at the  $\alpha = 0.05$  level ( $p\text{-value} = 6.74\text{E-}10$ ) and the  
 299 model explained 12.4% of deviance in the data.

300 We did not make inference on sonar received levels below 100 dB re. 1  $\mu\text{Pa}$  because Blainville's  
 301 beaked whales are unlikely to perceive MFAS below received levels of approximately 80  
 302 dB re. 1  $\mu\text{Pa}$  (Pacini et al., 2011) and because very little data (9 hrs, or 1% of the data  
 303 collected when MFAS was present) was collected at received levels below 100 dB re. 1  $\mu\text{Pa}$ . For  
 304 MFAS received levels between 100 and 190 dB re. 1  $\mu\text{Pa}$ , change in  $P(\text{GVP})$  was calculated  
 305 relative to the pre-activity baseline period ( $\Delta_{M3':M1'}$ ) and to the period when naval activity  
 306 was present on the range ( $\Delta_{M3':M2'}$ ; Fig. 4 & Fig. 5). At a received level of 150 dB,  $\Delta_{M3':M1'}$   
 307 was -92% (95% CI -100% - -87%) and  $\Delta_{M3':M2'}$  was -78% (95% CI -100% - -62%). Relative  
 308 to when only naval training is present,  $\Delta_{M3':M2'}$  predicts a 50% reduction in  $P(\text{GVP})$  at a  
 309 MFAS received level of 135 dB re 1  $\mu\text{Pa}$ .

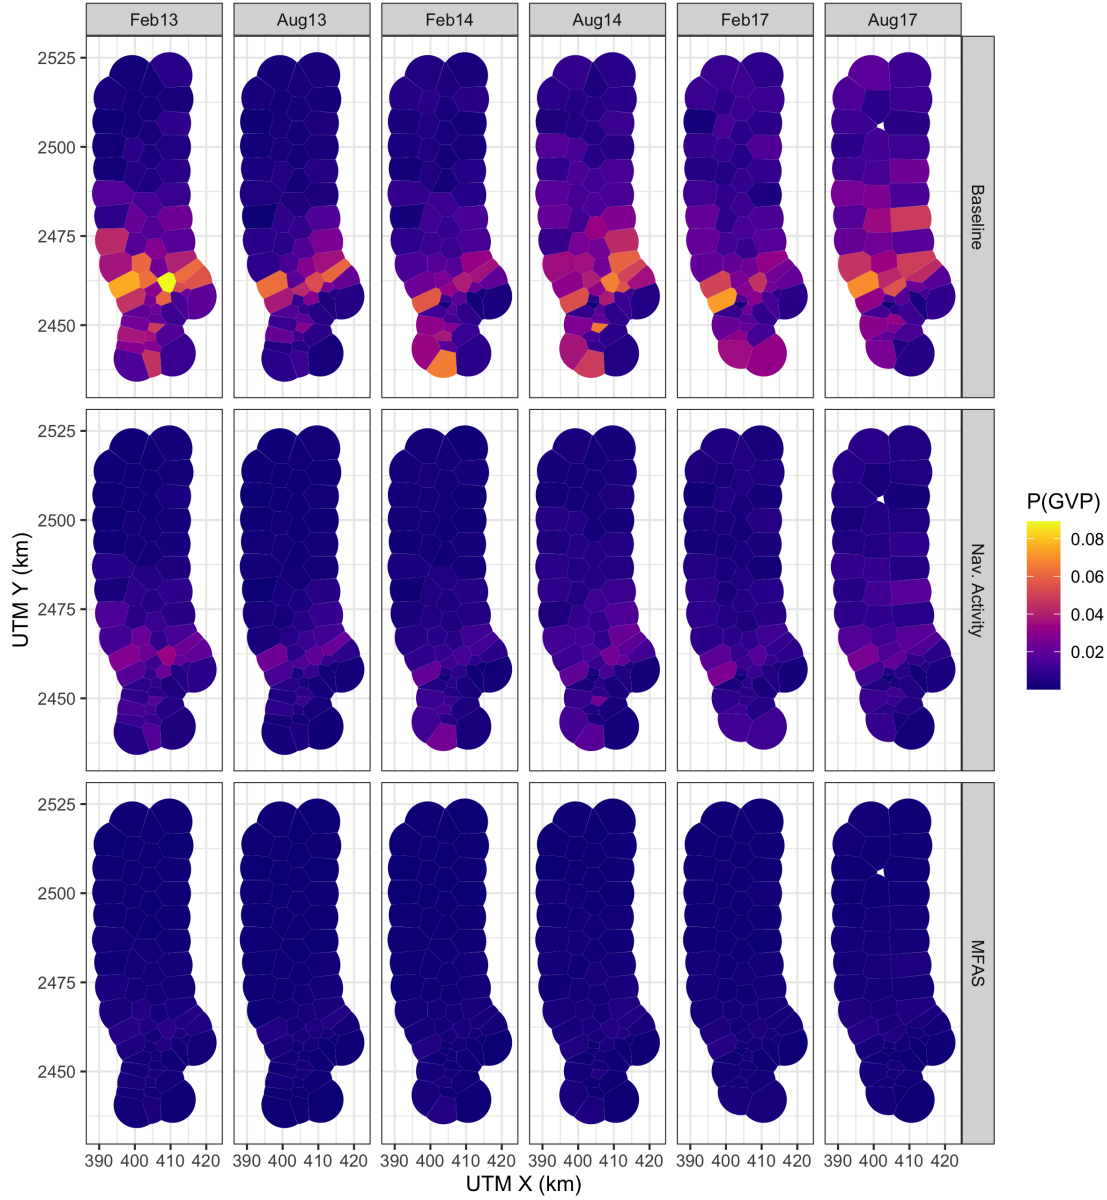

Figure 3: Map of expected probability of detecting a GVP (color scale) at each hydrophone during each SCC (columns) prior to the onset of naval training activity, during naval training activity when no MFAS was present, and during naval training activity when MFAS was present at a received level of 150 dB re. 1  $\mu\text{Pa}$  rms (rows).

Figure 4: Median (black line) and 95% CIs (gray shading) expected change in the probability of detecting a group vocal period (vertical axis) with increasing MFAS received level (horizontal axis) relative to when naval training activity but no MFAS is present on the range.

Figure 5: Median (black line) and 95% CIs (gray shading) expected change in the probability of detecting a group vocal period (vertical axis) with increasing MFAS received level (horizontal axis) relative to when neither naval training activity nor MFAS is present on the range.

## 4 Discussion

We used a series of three linked models to quantify the response of Blainville’s beaked whales to naval training exercises involving MFAS: the first model was fitted to pre-exercise baseline data, the second was fitted to data collected when naval training exercises were ongoing but no MFAS was present, and the third model was fitted to data collected during naval training exercises that used MFAS. We found that the probability of acoustic detections of Blainville’s beaked whales decreased when both naval training exercises and naval training exercises using MFAS were present (Fig. 4 and 5).

The methods presented here are spatially explicit and account for the spatial confounding of animal distribution and naval training activity. The data used in this study are from an undesigned experiment, where the spatial intensity of the treatments (naval activity and

MFAS) were not applied randomly with respect to either the study area or Blainville’s beaked whale presence. We did not want the spatial distribution of training exercises and MFAS to influence our understanding of the baseline spatial distribution of Blainville’s beaked whales. Due to the spatial confounding of animal distribution and naval training activity at PMRF, fitting a single model to all of the data would lead to underestimating the impact of sonar, since changes in distribution due to MFAS could be explained as spatial changes by the MRF (Appendix S3). Our three-stage modelling approach addresses this issue while propagating uncertainty between the models. To our knowledge, this is a novel application of GAMs.

The analytical approach outlined in this article could be applied to other species, regions, and types of disturbance where experimental design is not possible. The use of Markov random fields for the spatial term is useful for cases where exact distance data are not available, avoiding the use of continuous smoothers when true location data are not available. Shape-constrained smoothing is also well-suited to the kind of data we modelled here – ensuring that values can only stay constant or decrease over time (or any other covariate). Finally, the use of a multi-stage posterior sampling scheme extends to any situation where multiple models are fitted and the results of one part feed into another. Simulation-based approaches such as these bypass the need to derive (often complex) mathematical expressions (or shortcut them by assuming independence).

The expected change in the probability of a GVP when naval training was present and when MFAS was present included wide CIs (Figs. 4 and 5) with upper bounds (97.5% quantile) approaching a 100% reduction in expected  $P(\text{GVP})$  across received levels. This is likely due to the relatively small number of GVPs detected overall: GVPs were detected in only 1.2% of half-hour periods in the dataset. GVPs were detected in 0.7% of periods ( $n = 323$ ) when naval activity was present, and 0.2% ( $n = 48$ ) when MFAS was present. The small number of GVPs when MFAS was present – and therefore sparse coverage of data points across the range of received levels – makes it difficult to estimate the effect of MFAS received level

precisely. Additional data – particularly at relatively low source levels, where uncertainty is greatest – may reduce uncertainty in the expected probability of GVPs across different source levels. It is also possible that contextual factors that we did not include in this analysis, such as distance to sound source (DeRuiter et al., 2013; Falcone et al., 2017), may provide additional explanatory power and reduce uncertainty. It is also possible that the observed uncertainty reflects true individual variation in response due to variables like age and sex (see Harris et al., 2018, sec. 2.2 for a review of relevant publications).

In a regulatory context, a dose-response function as presented in Figs. 4 and 5 is often interpreted as representing the proportion of a population that responds (vertical axis) to a given received level (horizontal axis) (Tyack and Thomas, 2019). However, the metric used in this study – the change in the probability of detecting a GVP within a 30-min period – may not directly correspond to the proportion of the population that is affected. It may instead reflect a change in the proportion of time that all individuals in the population spent foraging. These two interpretations have different implications for understanding sub-lethal impacts of MFAS. In the former interpretation, given exposure to a certain received level, some of the population is affected and some of the population is not. In the latter, the entire exposed population is affected. With our data, we cannot distinguish between these possible scenarios.

Blainville’s beaked whales occur in multiple ocean basins and have been studied on U.S. Navy training ranges in both the Atlantic (AUTC) and the Pacific (PMRF) Oceans. The AUTC range is located in a deep basin bounded to the south, east, and west by shallow waters and with maximum depths of 2,000 m. In contrast, the PMRF occurs across a steep slope and into deep water, over 5,000 m in depth. Although the environments at PMRF and AUTC are different, the foraging dive behavior of Blainville’s beaked whales is similar at AUTC and PMRF: dives occur in waters over steep slopes with gradients ranging from 3-23%, although dives occur in deeper waters [2,000-3,000 m; Henderson et al. (2016)] at PMRF that at

373 AUTECH [500-1,300 m; MacLeod and Zuur (2005), Hazen et al. (2011)]. Resident Blainville's  
374 beaked whales off the island of Hawaii also occur in slightly shallower waters than at PMRF,  
375 from 980-1,410 m (Baird, 2011; Baird et al., 2008). Therefore it is likely the location of the  
376 mesopelagic scattering layer along the slope that drives the location of Blainville's beaked  
377 whales rather than the bathymetric depth; this is supported by the fact that dive depths  
378 are similar across areas, occurring on average down to 1,050-1,150 m for 46-60 min (Baird et  
379 al., 2008; Joyce et al., 2017; Schorr et al., 2009). Documented responses to MFAS activity  
380 are comparable at both ranges, with individuals and groups moving to the periphery of the  
381 range or off the range and returning 2-4 days after the cessation of the sonar (Joyce et al.,  
382 2019; Manzano-Roth et al., 2016; McCarthy et al., 2011).

383 In comparison to the risk function developed by Moretti et al. (2014) for Blainville's beaked  
384 whales at AUTECH, our risk function for PMRF predicts a more intense response to naval  
385 sonar. This may be because Moretti et al. were not able to explicitly account for the effects  
386 of naval training activities that did not include MFAS. Their baseline period consisted of  
387 19 hours of data before the onset of MFAS; as at PMRF, it is likely that training activities  
388 during this period included sound sources other than MFAS. Therefore, their risk function is  
389 probably more analogous to our expected change in the probability of a detection when MFAS  
390 is present relative to when naval training activity was present (Fig. 4). Future research will  
391 investigate the specific causes of changes in the probability of detecting GVPs before the onset  
392 of MFAS. The reduction in detection of foraging dives could be a response to general Naval  
393 training activity on the range, or to specific sound sources that have not previously been  
394 studied (e.g., acoustic countermeasures, U.S. Department of the Navy, 2008). Alternatively,  
395 it is possible that Blainville's beaked whales are semi-resident on the range and have become  
396 habituated to SCC activity; they may move off the range in anticipation of MFAS. Resident  
397 animals that are frequently exposed to training activity and transient animals that only  
398 encounter MFAS occasionally are likely to respond differently to sonar. It is not known how  
399 resident the Blainville's beaked whales are at PMRF, and there may be offshore animals as

well found on the northern hydrophones.

The similarities in Blainville’s beaked whale behavioral responses to Navy training activity across different ranges and environments at similar received levels may indicate the intrinsic nature of the response. The findings presented here and in Moretti et al. (2014) may be applicable to other species and regions, though species-specific dive behaviors and regional differences in oceanography likely modulate the impact of MFAS. Conducting a similar analysis of Cuvier’s beaked whale responses at the Southern California Anti-Submarine Warfare Range (SOAR) would further support this assessment; existing findings already demonstrate that Cuvier’s respond in a similar manner by reducing their foraging dives and moving away from the ensonified area (DeRuiter et al., 2013; Falcone et al., 2017).

## S1: Uncertainty estimation details

We used posterior simulation to propagate uncertainty through **M1**, **M2**, and **M3**. Each model was fitted via restricted maximum likelihood (REML), so the resulting estimates were empirical Bayes estimates. In this case we generated 1000 samples from the (approximately multivariate normal) posterior of the model parameters. We generated a sample of the model parameters,  $\boldsymbol{\beta}^* \sim \text{MVN}(\hat{\boldsymbol{\beta}}, \mathbf{V}_{\hat{\boldsymbol{\beta}}})$ , where  $\hat{\boldsymbol{\beta}}$  is the estimate of the model coefficients and  $\mathbf{V}_{\hat{\boldsymbol{\beta}}}$  is the posterior covariance matrix. Here the  $\boldsymbol{\beta}$  for each model included the coefficients for the smooth terms in the model and fixed effects (e.g., intercept) if present. We then used the matrix that maps the model parameters to the predictions on the linear predictor scale ( $\mathbf{X}_p$ ; Wood et al. 2017; section 7.2.6), along with the inverse link function, to generate predictions for each posterior sample. Denoting the vector of predictions  $\boldsymbol{\mu}^*$ , we calculate as follows:

$$\boldsymbol{\mu}^* = g^{-1}(\boldsymbol{\eta}^*) = g^{-1}(\mathbf{X}_p \boldsymbol{\beta}^* + \boldsymbol{\xi}),$$

where  $g$  was the link function,  $\boldsymbol{\eta}^*$  was the linear predictor and  $\boldsymbol{\xi}$  was any offset used by this prediction. Variance estimates can be obtained by taking the empirical variance of the resulting predictions (Wood et al. 2017; section 7.2.6). The prediction grid contained all possible combinations of covariates within the realized covariate space; i.e., each hydrophone for each SCC with associated location, hydrophone depth, and area of the tessellation tile, presence/absence of naval activity, and, if naval activity was present, then either sonar absence or sonar received level between 35 and 190 dB in intervals of 5 dB. This procedure was repeated for each model, with refitting to updated offsets from the previous model.

An algorithm for calculating the variance from our multi-stage approach is as follows. First define  $N_b$  as the number of samples to take ( $N_b=1000$  here), let  $\mathbf{X}_{p, \mathbf{M}j}$  for  $j = 1, 2, 3$  be the

matrix that maps coefficients to the predictions for model  $M_j$ . For  $N_b$  times:

1. Draw a sample from the posterior of  $M1$ :  $\tilde{\beta}_{M1} \sim \text{MVN}(\hat{\beta}_{M1}, \mathbf{V}_{M1})$ .
2. Calculate a new offset for  $M2$ ,  $\tilde{\xi}_{M1} = \mathbf{X}_{p,M1}\tilde{\beta}_{M1} + \log_e \mathbf{A}$ .
3. Refit  $M2$  with  $\tilde{\xi}_{M1}$  as the offset, to obtain  $M2'$ .
4. Draw a sample from the posterior of  $M2'$ :  $\tilde{\beta}_{M2'} \sim \text{MVN}(\hat{\beta}_{M2'}, \mathbf{V}_{M2'})$
5. Calculate a new offset for  $M3$ ,  $\tilde{\xi}_{M2} = \mathbf{X}_{p,M2}\tilde{\beta}_{M2'} + \tilde{\xi}_{M1}$  (predictions for the sonar data locations for  $M2'$ ).
6. Refit  $M3$  with offset  $\tilde{\xi}_{M2}$  to obtain  $M3'$ .
7. Predict  $\mu_{M1'}$ ,  $\mu_{M2'}$ , and  $\mu_{M3'}$  over prediction grid and store them.

We then calculated summary statistics (means and variances) of the  $N_b$  values of  $\mu_{M1'}$ ,  $\mu_{M2'}$ , and  $\mu_{M3'}$  we generated. The empirical variance of the  $N_b$  values of  $\mu_{M3'}$  gave the uncertainty, incorporating components from all three models. We took appropriate pointwise quantiles (e.g., 2.5<sup>th</sup> and 97.5<sup>th</sup> for a 95% interval) to form confidence bands for the functional relationships between sonar received level and estimated probability of detecting GVPs.

## S2: Supplementary Tables and Figures

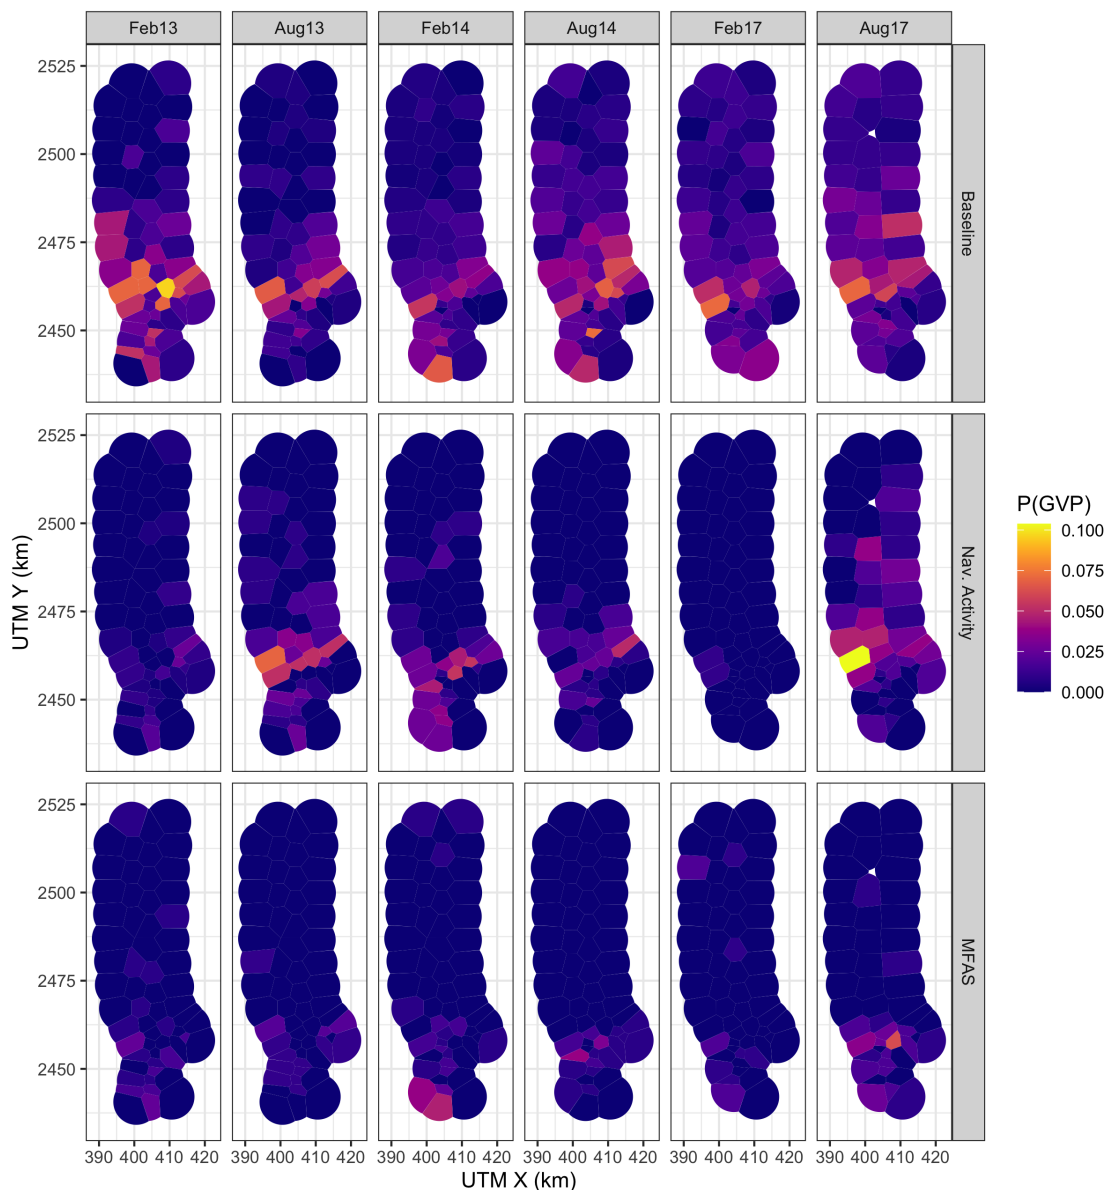

Figure S2.1: Map of observed probability of detecting a GVP at each hydrophone (color scale) during the baseline period, when naval activity was present, and when MFAS was present (rows) for each SCC (columns). Note that values of the probability of detecting a GVP are not corrected for effort (size of the hydrophone tile).

Figure S2.2: Median received level (dB re. 1  $\mu$ Pa) when MFAS was present (color scale) for all hydrophones and SCCs.

Figure S2.3: Boxplot of observed probability of a GVP across all hydrophones and SCCs (vertical axis) during baseline period, when naval activity was present, and when MFAS was present (horizontal axis).

Figure S2.4: PMRF range tessellations for each of six recorded SCCs. Black lines indicate boundaries of hydrophone tiles. Black dots indicate approximate hydrophone locations.

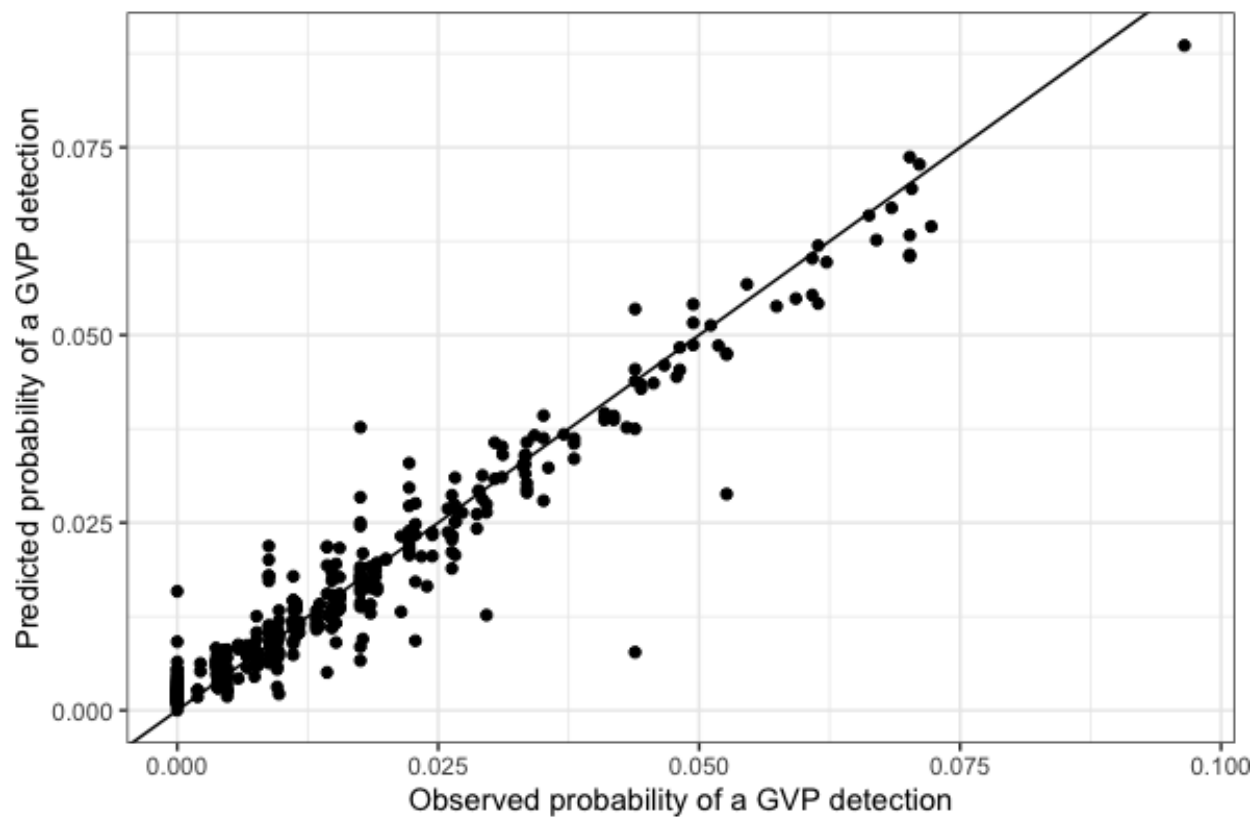

Figure S2.5: Observed (horizontal axis) versus M1 predicted (vertical axis) probability of detecting a GVP at each hydrophone during the baseline period.

Figure S2.6: Spline on depth from M1.

Figure S2.7: Spline on maximum received level from M3.

### S3: Single GAM

A single GAM could be used to quantify the effect of naval sonar on Blainville’s beaked whales. Here, we present such a model and compare the results to the results obtained using the multi-stage model presented in the main text of the manuscript.

We modelled the probability of a GVP at tile  $i$  in SCC  $s$  at time  $t$  as a Bernoulli trial:

$\text{GVP}_{i,s,t} \sim \text{Bin}(1, \mu_{i,s,t})$ . The linear predictor for on the logit scale was given as:

$$\text{logit}(\mu_{i,s,t}) = \beta_0 + \beta_1 \text{NavTrain}_t + f(\text{MRF}_{i,s}) + f(\text{Depth}_i) + f(\text{MaxRL}_i, t) \text{Sonar}_t + \log_e A_i$$

where  $\beta_0$  is an intercept,  $\beta_1 \text{NavTrain}_t$  is the effect of naval training times an indicator variable for whether naval training was present or absent at time  $t$ ,  $f(\text{MRF}_{i,s})$  denotes the Markov random field used to smooth space,  $f(\text{Depth}_i)$  is a smooth of depth (using a thin plate spline; Wood et al. 2003),  $f(\text{MaxRL}_i, t) \text{Sonar}_t$  is a monotonically decreasing smooth of sonar received level (using a thin plate spline) times an indicator variable for whether sonar was present or absent at time  $t$ , and  $\log_e A_i$  is an offset for the area (in  $\text{km}^2$ ) of each tile,  $A_i$ .

We fit the model using `scam` (Pya et al. 2015).

This single GAM predicts a 64% decrease in  $P(\text{GVP})$  when naval training is present compared to the baseline period, which is the same decrease predicted by the multi-stage GAM. However, the single GAM predicts that at a MFAS received level of 150 dB re 1  $\mu\text{Pa}$ ,  $P(\text{GVP})$  will decrease by 64% relative to when only naval training is present, whereas the multi-stage model predicts a decrease of 78%. Similarly, the single GAM predicts that at a MFAS received level of 150 dB re 1  $\mu\text{Pa}$ ,  $P(\text{GVP})$  will decrease by 87% relative to baseline, whereas the multi-stage model predicts a 92% decrease. Relative to when only naval training is present, the single GAM predicts a 50% reduction in  $P(\text{GVP})$  at a MFAS received level of 144 dB, whereas the multi-stage model predicts a 50% reduction at a

MFAS received level of 135 dB re 1  $\mu$ Pa.

The major difference between this single GAM and the multi-stage model presented in the main text of the manuscript is that here, the spatial smooth is constructed using data from the baseline, naval training, and MFAS periods of each SCC. Therefore, the spatial distribution of MFAS may influence the predicted distribution of Blainville's beaked whales. As expected, using a single GAM leads to underestimates of the impact of sonar, since changes in distribution due to MFAS are not captured by the MRF.

Figure S3.1: Results from a single GAM: Median (black line) expected change in the probability of detecting a group vocal period (vertical axis) with increasing MFAS received level (horizontal axis) relative to when naval training activity but no MFAS is present on the range.

Figure S3.2: Results from a single GAM: Median (black line) expected change in the probability of detecting a group vocal period (vertical axis) with increasing MFAS received level (horizontal axis) relative to when neither naval training activity nor MFAS is present on the range.
